

Non-Gaussianities in models with a varying inflaton decay rate

Matias Zaldarriaga

(February 2, 2008. To be submitted to Phys. Rev. D.)

We consider the expected level of primordial non-Gaussianities in models in which density perturbations are produced by spatial fluctuations in the decay rate of the inflaton. We consider both the non-Gaussianities resulting from the self-couplings of the field that controls the decay rate as well as from the non-linear relation between field and curvature perturbations. We show that in these scenario non-Gaussianities are of the “local” form, *ie* well described by the ansatz $\mathcal{R} = \mathcal{R}_g + f_{NL}^{\mathcal{R}}(\mathcal{R}_g^2 - \langle \mathcal{R}_g^2 \rangle)$. This is a consequence of the fact that they were created when modes were already outside the horizon. We show that $f_{NL}^{\mathcal{R}}$ is naturally of order a few in these models, much larger than what is expected in the standard one field models of inflation ($f_{NL}^{\mathcal{R}} \sim 10^{-2}$) and possibly accessible to observations.

I. INTRODUCTION

It is safe to say that the era of “precision cosmology” is upon us. The latest CMB anisotropy measurements from WMAP [1] have underscored how successful our standard cosmological model is. Many of the parameters describing the matter content of the universe are now firmly established [2]. Moreover the conclusion that the structure we observe in the universe grew from seeds that were in place much before recombination seems almost unavoidable [3].

The leading scenario for explaining how these initial seeds were created is inflation. In this picture the universe went through a period of accelerated expansion very early on. During inflation the energy density is dominated by the potential energy of a slowly rolling scalar field, the inflaton. During this period quantum fluctuations in the inflaton field were stretched outside the horizon and became the seeds for structure. The predictions from this scenario have been worked out to great detail in the last few decades (see for example [4,5] and references therein). Basically most models of inflation predict a scale invariant spectrum of Gaussian fluctuations of the curvature. A stochastic background of gravitational waves is also predicted, although its level is quite uncertain.

The Gaussianity of the perturbations in the standard picture are a consequence of the slow-roll conditions on the inflaton potential. These conditions are required for the field to be slowly rolling and the universe to be inflating. The required flatness of the potential implies that non-Gaussianities are very small, probably below what could be observable (see [6] and references therein). If the inflaton field has several components it is possible to construct models with larger non-Gaussianities even in the adiabatic component. Basically large couplings are allowed for the “isocurvature” directions which if suitably coupled to the adiabatic direction could lead to non-Gaussianities in that direction as well (eg. [7–9]).

There are basically two modifications of the standard inflationary scenario in which the curvature perturbations we observe today were not created during inflaton

but later. These are the “curvaton” scenario [10–15] and the scenario proposed in [16] (see also [17,18]). Both require the existence of other light fields during inflation. In the “curvaton” model one of these fields eventually comes to dominate or at least be a significant contributor to the energy density and reheats the universe again. The curvature perturbations we observe are a result of the fluctuations in the curvaton field as opposed to the inflaton. Fluctuations in the curvaton were still produced during inflation by the standard mechanism but they get converted into curvature perturbations when the curvaton becomes dominant.

The scenario presented in [16] is different. At the end of inflation the energy stored in the inflaton has to be converted into normal particles, reheating the universe and starting the standard phase of the hot big bang. In [16] we suggested that if the efficiency with which the inflaton reheats the universe, its decay rate Γ varied in space, density perturbations would be generated during reheating independently of those generated by the standard inflationary mechanism. If two different regions of the universe had different Γ s then effectively the inflaton would decay into radiation first in one region and then in the other. During the time one region is filled with radiation while the other one is not, the universe expands at a different rate in each region, resulting in density perturbations when reheating is finished. In a similar spirit, the in-homogeneous freeze out of an unstable particle whose mass and decay rate are determined by a light scalar field and that briefly dominates the energy density would also lead to density perturbations [17].

The motivation for these new scenarios is that in general the decay rate of the inflaton as well as the masses and decay rates of particles are determined by the expectation values of scalar fields. If those scalar fields were light during inflation they fluctuated, which lead to density perturbations.

In this paper we will analyze under what conditions the fluctuations in the scenario of [16] are Gaussian. For example, the potential for the fields that determine the inflaton decay rate do not have to satisfy any slow-roll conditions so one might expect their fluctuations to be

significantly non-Gaussian. We will find that generically we predict non-Gaussianities that are larger than those predicted by the standard inflationary model although within the observational bounds. Moreover these additional non-Gaussianities could be accesible to future experiments. There are two avenues for searching for primordial non-Gaussianities observationally, studies of the CMB [19] and studies of Large Scale structure as traced say by galaxies or weak lensing (see [20] for a comprehensive review of non-Gaussianity in the context of Large Scale Structure).

The paper is organized as follows. In §II we summarize how the curvature perturbations are generated in this scenario. In §III we discuss the different sources of non-Gaussianities and finally in §IV we make contact with observations.

II. DENSITY PERTURBATIONS IN THE NEW SCENARIO

The decay rate of the inflaton (which we call S) can be written schematically as,

$$\Gamma = m_S g^2 K, \quad (1)$$

where m_S is the mass of the inflaton, g its coupling constant and K are kinematic suppression factors of the form $(1 - m_d^2/m_S^2)$ where m_d stands for the masses of the decay products which are also functions of the scalar fields. All three quantities, m_S , g and K are functions of the scalar fields in the theory so clearly there are a wide rage of possible specific models in which Γ has a different dependance on the fields

During inflation the light fields ϕ_i have expectation values $\bar{\phi}_i$ around which they fluctuate. To keep our discussion generic we will express the decay rate as an expansion in powers of those fluctuations,

$$\Gamma = \Gamma_0 + \frac{\partial \Gamma}{\partial \phi_i} \delta \phi_i + \frac{1}{2} \frac{\partial^2 \Gamma}{\partial \phi_i \partial \phi_j} \delta \phi_i \delta \phi_j + \dots \quad (2)$$

In [16] it was shown that to linear order in the decay rate fluctuations $\delta \Gamma / \Gamma$ curvature fluctuations $\mathcal{R}$ are generated. We found,

$$\mathcal{R} = -\alpha \frac{\delta \Gamma}{\bar{\Gamma}} \quad (3)$$

where the constant α depends on the ratio of $\bar{\Gamma}$ to the Hubble expansion at the end of inflation (H). As $\bar{\Gamma}/H$ increases α decreases. It is clear for example that in the limit $\Gamma/H \gg 1$ reheating happens almost instantaneously in all regions regardless of the value of Γ and thus the resulting density perturbations will be very small. In [16] it was proved that in the limit when $\bar{\Gamma} \ll H$

$$\mathcal{R} = -\frac{1}{6} \frac{\delta \Gamma}{\bar{\Gamma}}. \quad (4)$$

We will now present a different derivation of the same result that will allow us to extend our treatment to investigate non-Gaussianities in a later section.

We first consider reheating in a homogeneous universe, ie with a constant Γ . We will treat the inflation as non-relativistic matter when it oscillates around the minimum of its potential after inflation ends. We will call ϵ_m the energy density in the oscillating inflaton. During reheating, the energy density in the inflaton is converted into radiation (with energy density ϵ_r). The background metric is that of a flat FRW universe, $ds^2 = -dt^2 + a^2(t)dx^2$, a is the scale factor. The Hubble constant is $H = \dot{a}/a$, with $\dot{} \equiv d/dt$ where t is the time. The evolution equations are

$$\begin{aligned} \dot{\epsilon}_m &= -3H\epsilon_m - \Gamma\epsilon_m, \\ \dot{\epsilon}_r &= -4H\epsilon_r + \Gamma\epsilon_m, \\ H^2 &= \frac{8\pi G}{3}(\epsilon_r + \epsilon_m) \end{aligned} \quad (5)$$

After inflation the fraction $x \equiv \epsilon_m/(\epsilon_m + \epsilon_r) = 1$, and remains constant until it suddenly drops to zero when $H \sim \Gamma$. After that point $a \propto t^{1/2}$.

The key point to understand is that universes with different values of Γ will have expanded by different amounts by the time reheating is over. In figure 1 we show the final scale factor as a function of Γ . We plot $\ln(g) = \ln(at^{-1/2})$ vs. $\ln(\Gamma/H)$ where H is the expansion rate at the end of inflation. The asymptote at $\Gamma/H \rightarrow 0$ corresponds to $g \propto \Gamma^{-1/6}$, a result that can be obtained analytically [21].

FIG. 1. Expansion factor normalization g as a function of Γ/H after reheating. The curve was obtained by solving equations (5) numerically starting with $\epsilon_r = 0$ and Hubble expansion H at the initial time.

After reheating is over the metric is $ds^2 = -dt^2 + g^2(\Gamma)tdx^2$ where $g^2(\Gamma)$ is the function plotted in figure 1. To obtain the density perturbations in our model we just need to promote Γ to a function of position,

$$ds^2 = -dt^2 + g^2(\Gamma(x))tdx^2. \quad (6)$$

This metric will be a solution of Einstein's equations if Γ is sufficiently slowly varying, that is to say if Γ changes on scales much larger than the horizon. Clearly this is a very good approximation as we are interested in changes of Γ over scales that are of cosmological interest *today*. It is important to realize that we have not made an expansion in powers of $\delta\Gamma/\Gamma$, we have just assumed that the gradients are small. As a result we can use the above metric to calculate quantities to higher order in $\delta\Gamma/\Gamma$ as long as we do so when the variations of Γ are on super-horizon scales.

To make contact with observations we need to calculate the spatial curvature of surfaces of constant time. For the metric in equation (6) we obtain [5,23],

$$\mathcal{R} = \frac{\delta g}{g} = -\alpha \frac{\delta \Gamma}{\Gamma}. \quad (7)$$

where $\alpha = -d \ln g / d \ln a$ is just minus the slope of the curve in figure 1 at the appropriate value of Γ . This result was already obtained in [16] by the standard perturbation theory methods. In linear perturbation theory the variable $\mathcal{R}$ is related to the curvature of hypersurfaces of constant t ($R^{(3)}$) by (see for example [5])

$$R^{(3)} = -\frac{4}{a^2} \nabla^2 \mathcal{R}. \quad (8)$$

We will generalize this expression to include higher order terms later.

A few things are worth noting. If after reheating the composition is the same everywhere, if we are dealing with adiabatic perturbations, the universe will expand by the same amount everywhere. As a result ratios of the scale factor between different places are constant in time, and thus $\mathcal{R}$ is constant. Certainly because the couplings and masses of particles are different in different places at reheating in this scenario there is the possibility of generating different ratios of abundances of particles as a function of location. Thus our scenario can create “isocurvature” density perturbations as well. This is similar to what happens in the “curvaton” scenario. Although this is a possibility, it is rather unlikely. Isocurvature perturbations could result if either there is varying decay into species out of equilibrium or if the decay of the inflaton lead to baryon asymmetry or lepton asymmetry fluctuations.

III. NON-GAUSSIANITIES

In this section we will discuss the level of non-Gaussianities that we can expect in this scenario. We will consider the curvature perturbations $\mathcal{R}$ and write,

$$\begin{aligned} \mathcal{R} = & \mathcal{R}_{g1} + f_{NL}^{\mathcal{R}_{g1}} (\mathcal{R}_{g1}^2 - \langle \mathcal{R}_{g1}^2 \rangle) \\ & + f_{NL}^{\mathcal{R}_{g2}} (\mathcal{R}_{g2}^2 - \langle \mathcal{R}_{g2}^2 \rangle) + f_{NL}^{\mathcal{R}_{g1-g2}} \mathcal{R}_{g1} \mathcal{R}_{g2} + \dots \end{aligned} \quad (9)$$

where $\mathcal{R}_{1g}$ and $\mathcal{R}_{2g}$ are Gaussian random fields and the $f_{NL}^{\mathcal{R}}$ control the level of non-Gaussianities. We have departed slightly from the notation of Komatsu & Spergel [19] by working with the curvature $\mathcal{R}$ rather than the gravitational potential because $\mathcal{R}$ is constant outside the horizon while the gravitational potential evolves whenever the effective equation of state of the universe changes. We have also allowed for the possibility that more than one Gaussian field $\mathcal{R}_{1g}$ and $\mathcal{R}_{2g}$ enter into the quadratic corrections. As equation (2) makes clear, this could happen if more than one field ϕ_i determined the decay rate of the inflaton. The first thing to point out is that the extra terms do not enter into the calculation of the three point function to lowest order in f_{NL} so observationally they are not relevant. Higher order terms are suppressed by extra powers of $\mathcal{R} \sim 10^{-5}$.

There are several sources for the non-Gaussianities in $\mathcal{R}$. The fluctuations $\delta\phi_i$ in equation (2) could themselves be non-Gaussian. Even if those were Gaussian the relation between $\delta\phi_i$ and the decay rate Γ in (2) is non-linear. The fact that Γ is by definition positive means that the relation *cannot* be purely linear, the size of those non-linearities however varies from model to model. Moreover as shown in the previous section $g(\Gamma)$ is a non-linear function of Γ which leads to additional non-Gaussianities. We will consider the different cases in turn.

A. Gaussian $\delta\phi_i$ fluctuations

We start by considering a simple example in which there is a field ϕ that sets the coupling of one of the channels through which the inflation can decay and that in addition there is an extra channel that does not fluctuate. This example was considered in [16]. The decay rate can be written as,

$$\begin{aligned} \Gamma = & \Gamma_0 + \Gamma_1 \left(\frac{\phi}{\bar{\phi}} \right)^2 \\ = & \Gamma_0 + \Gamma_1 \left(1 + \frac{\delta\phi}{\bar{\phi}} \right)^2, \end{aligned} \quad (10)$$

so that

$$\begin{aligned} \frac{\Gamma - \bar{\Gamma}}{\bar{\Gamma}} = & \frac{\Gamma_1}{\bar{\Gamma}} \left(2 \frac{\delta\phi}{\bar{\phi}} + \frac{\delta\phi^2 - \langle \delta\phi^2 \rangle}{\bar{\phi}^2} \right) \\ \bar{\Gamma} = & \Gamma_0 + \Gamma_1 \left(1 + \frac{\langle \delta\phi^2 \rangle}{\bar{\phi}^2} \right). \end{aligned} \quad (11)$$

The ratio $\Gamma_1/\bar{\Gamma}$ determines the fraction of the decay rate that is controlled by ϕ .

We first consider the transformation between Γ and $\mathcal{R}$ only to linear order,

$$\mathcal{R} = -\alpha \frac{\Gamma_1}{\bar{\Gamma}} \left(2 \frac{\delta\phi}{\bar{\phi}} + \frac{\delta\phi^2 - \langle \delta\phi^2 \rangle}{\bar{\phi}^2} \right) \quad (12)$$

where α is less than $1/6$ (see figure 1). We can rewrite equation (12) as

$$\begin{aligned} \mathcal{R} &= \mathcal{R}_g + f_{NL}^{\mathcal{R}} (\mathcal{R}_g^2 - \langle \mathcal{R}_g^2 \rangle) \\ f_{NL}^{\mathcal{R}} &= -\frac{\bar{\Gamma}}{4\Gamma_1\alpha} \end{aligned} \quad (13)$$

Equation (13) shows that the smaller the efficiency of our mechanism of generating density perturbations, the larger the $f_{NL}^{\mathcal{R}}$. The inefficiency in the present example comes from two sources, a small value of α which occurs when the decay rate of the inflaton is not much smaller than the Hubble constant at the end of inflation. The other source of inefficiency comes from the fact that the field only controls part of the channels through which the inflaton can decay. Again, the smaller the fraction of the decay rate controlled by ϕ , the larger the non-Gaussianities.

The origin of the relation between inefficiency and non-Gaussianities is simple to understand. If we keep the level of fluctuations in $\mathcal{R}$ fixed, which we must to explain the observed level of density perturbations, as we decrease the efficiency we must increase the level of $\delta\phi/\bar{\phi}$. As a result quadratic terms in $\delta\phi/\bar{\phi}$ become more important relative to the linear term and thus the non-Gaussianity increases. As this argument makes clear, the relation between inefficiency and non-Gaussianity is more general than the particular example we have chosen for the form of the decay rate.

We now need to consider the fact that the relation between the decay rate and the final curvature is non-linear, that is the final value of the scale factor is a non-linear function of the Γ as figure 1 shows. To be more specific we will calculate the curvature of the hypersurfaces of constant time in the metric of equation (6). We can do so without doing a linear approximation in $\delta\Gamma/\Gamma$ although we are calculating only the leading contribution in an expansion in terms of the horizon scale over the scale of variation of Γ . We get,

$$R^{(3)} = -\frac{4}{a^2} [\nabla^2 \ln g - \|\nabla \ln g\|^2], \quad (14)$$

where $a = g(x)t^{1/2}$. The first term is the direct generalization of the linear perturbation formula, with $\mathcal{R} = \ln(g/\bar{g})$. As it should be only spatial changes the logarithm of g signal curvature perturbation.

We are interested in calculating the curvature to second order in $\delta\Gamma/\Gamma$. There will be two contributions, one from expanding the $\ln g$ to second order and the other from the second term in equation (14). These second term arises because General Relativity itself is a non-linear theory. We will comment on these shortly. For the moment we focus on the first term. With the definition $\mathcal{R} = \ln(g/\bar{g})$ we have,

$$\mathcal{R} = -\alpha \frac{\delta\Gamma}{\bar{\Gamma}} + \frac{\alpha + \beta}{2} \frac{\delta\Gamma^2 - \langle \delta\Gamma^2 \rangle}{\bar{\Gamma}} + \dots \quad (15)$$

where $\alpha = -d \ln a / d \ln \Gamma$, the slope of the curve in figure 1 and β is the curvature $\beta = d^2 \ln a / d \ln \Gamma^2$. Thus the fact that the relation between Γ and total expansion is non-linear adds an additional contribution to $f_{NL}^{\mathcal{R}}$,

$$f_{NL}^{\mathcal{R}} = \frac{\alpha + \beta}{2\alpha^2} \quad (16)$$

This contribution is at least equal to $f_{NL}^{\mathcal{R}} = 3$ and increases as the process becomes more inefficient ($\alpha < 1/6$) because $\delta\Gamma/\bar{\Gamma}$ increases to produce the same level of curvature fluctuations. Note however that these non-Gaussianities do not include the extra enhancement factor $\bar{\Gamma}/\Gamma_1$. The point is that the inefficiency in the translation between $\delta\Gamma/\bar{\Gamma}$ and $\delta\phi/\bar{\phi}$ makes $\delta\phi/\bar{\phi}$ larger and thus terms quadratic in $\delta\phi/\bar{\phi}$ lead to larger non-Gaussianities than terms arising from $\delta\Gamma/\bar{\Gamma}$ corrections.

We now comment on the second term in equation (14). It contributes an additional effect that leads to an $f_{NL}^{\mathcal{R}} \sim -1$, thus it is subdominant to what comes from the first term and is independent of α . Moreover as the modes enter the horizon additional non-Gaussianities from non-linearities caused by term we have neglected in Einstein's equations will develop. Perhaps more importantly one should solve for the observables (such as the CMB anisotropies) to second order in $\mathcal{R}$ to catch all the terms that contribute at the level of $f_{NL}^{\mathcal{R}} \sim 1$. $R^{(3)}$ may not be the quantity directly relevant to observations. It is beyond the scope of this paper to characterize all these terms or to extend the usual linear treatment of CMB anisotropies to include them. *What we have calculated should be interpreted as corrections in addition to what GR already gives.*

Finally we want to comment on the possibility that the quadratic corrections to the Gaussian curvature are not proportional to the linear contribution squared. In our scenario this happens trivially when more than one light field determines Γ . For example if

$$\Gamma = \Gamma_0 + \Gamma_1 \left(\frac{\phi_1}{\bar{\phi}_1} \right)^2 + \Gamma_2 \left(\frac{\phi_2}{\bar{\phi}_2} \right)^2 \quad (17)$$

then there are two different Gaussian fields that enter in the quadratic corrections,

$$\begin{aligned} \mathcal{R}_{g1} &= \frac{2\Gamma_1}{\bar{\Gamma}} \frac{\delta\phi_1}{\bar{\phi}_1} + \frac{2\Gamma_2}{\bar{\Gamma}} \frac{\delta\phi_2}{\bar{\phi}_2} \\ \mathcal{R}_{g2} &= \frac{2\Gamma_2}{\bar{\Gamma}} \frac{\delta\phi_1}{\bar{\phi}_1} - \frac{2\Gamma_1}{\bar{\Gamma}} \frac{\delta\phi_2}{\bar{\phi}_2}. \end{aligned} \quad (18)$$

The amplitudes of the non-linear terms defined in equation (9) are,

$$f_{NL}^{\mathcal{R}_{g1}} = \frac{[(\Gamma_1/\bar{\Gamma})^2 + (\Gamma_2/\bar{\Gamma})^2]^{-1/2}}{4} (\sin^3 \theta + \cos^3 \theta) \quad (19)$$

$$f_{NL}^{\mathcal{R}_{g^2}} = \frac{[(\Gamma_1/\bar{\Gamma})^2 + (\Gamma_2/\bar{\Gamma})^2]^{-1/2}}{4} \sin \theta \cos \theta (\sin \theta + \cos \theta)$$

$$f_{NL}^{\mathcal{R}_{g^1-g^2}} = \frac{[(\Gamma_1/\bar{\Gamma})^2 + (\Gamma_2/\bar{\Gamma})^2]^{-1/2}}{2} \sin \theta \cos \theta (\sin \theta - \cos \theta),$$

with $\cos \theta = \Gamma_1/[\Gamma_1^2 + \Gamma_2^2]^{1/2}$ and $\sin \theta = \Gamma_2/[\Gamma_1^2 + \Gamma_2^2]^{1/2}$. Other than the slight redefinition of $f_{NL}^{\mathcal{R}_{g^1}}$ these additional terms are unimportant if we are only interested in calculating effects to first order in the f_{NL} s. The other terms will only enter at higher orders and will be thus suppressed by extra powers of $\mathcal{R} \sim 10^{-5}$. Generically then, modifications of the standard f_{NL} form, $\mathcal{R} = \mathcal{R}_g + f_{NL}^{\mathcal{R}}(\mathcal{R}_g^2 - \langle \mathcal{R}_g^2 \rangle)$, are what is expected in our scenario. It turns out this remains true even when self couplings of the field are considered.

B. non-Gaussian $\delta\phi_i$ fluctuations

In this section we calculate the non-Gaussianities in the $\delta\phi$ fluctuations if the potential for ϕ is not quadratic. We will follow [6], although our situation is much simpler because the field makes a negligible contribution to the energy density so we do not need to take into account perturbations in the metric. The action for $\delta\phi$ is,

$$S = \int a^4 d^3x d\eta \left[\frac{(\delta\phi')^2 - (\nabla\delta\phi)^2}{2a^2} - \frac{V^{(2)}}{2!}\delta\phi^2 - \frac{V^{(3)}}{3!}\delta\phi^3 - \frac{V^{(4)}}{4!}\delta\phi^4 - \dots \right]. \quad (20)$$

We denote $V^{(k)}$ the k th derivative of the potential.

We quantize the field in the usual way to obtain,

$$\hat{\delta\phi} = \int \frac{d^3\mathbf{k}}{(2\pi)^3} [f(k, \eta) e^{-i\mathbf{k}\cdot\mathbf{x}} a_{\mathbf{k}} + f^*(k, \eta) e^{i\mathbf{k}\cdot\mathbf{x}} a_{\mathbf{k}}^\dagger] \quad (21)$$

where $[a_{\mathbf{k}_1}, a_{\mathbf{k}_2}^\dagger] = (2\pi)^3 \delta^D(\mathbf{k}_1 - \mathbf{k}_2)$ and $f(k, \eta)$ are the mode functions. For the massless field in de-Sitter space ($V^{(2)} = 0$ and H constant),

$$f(k, \eta) = \frac{H}{\sqrt{2k^3}} (1 - ik\eta) e^{ik\eta} \quad (22)$$

We want to calculate the N-point function $g_N(1, 2, \dots, N)$ for N points at the time of reheating,

$$g_N(1, 2, \dots, N) = \langle 0 | U^{-1} \hat{\delta\phi}(1) \hat{\delta\phi}(2) \dots \hat{\delta\phi}(N) U | 0 \rangle$$

$$U = \exp \left[-i \int_{t_0}^{t_{reh}} \hat{H}_{int} dt \right] \quad (23)$$

where t_{reh} is the time of reheating, t_0 is some early initial time and $\hat{H}_{int} = \frac{V^{(3)}}{3!} \delta\phi^3 + \frac{V^{(4)}}{4!} \delta\phi^4 + \dots$ is the Hamiltonian in the interaction picture. To lowest order in $\hat{H}_{int}$ this gives,

$$g_N(1, \dots, N) = -i \int dt \langle 0 | [\hat{\delta\phi}(1) \hat{\delta\phi}(2) \dots \hat{\delta\phi}(N), \hat{H}_{int}] | 0 \rangle$$

The N-point function is most easily expressed in Fourier space. For a massless field in de-Sitter we obtain,

$$\tilde{g}(\mathbf{k}_1, \dots, \mathbf{k}_N) = (2\pi)^3 \delta^D(\mathbf{k}_1 + \dots + \mathbf{k}_N) \times$$

$$V^{(N)} \frac{H^{2N} k_t^3}{\prod_i 2k_i^3} I_N(k_1, k_2, \dots, k_N) \quad (24)$$

$$I_N = \int_{-\infty}^{\eta_{reh}} \frac{d\eta}{k_t^3 \eta^4} 2\text{Re}[-i(1 - ik_1\eta) \dots (1 - ik_N\eta) e^{ik_t\eta}]$$

with $k_t = k_1 + k_2 + \dots + k_N$ and η_{reh} is the conformal time of reheating. Following [6] to project onto the vacuum of the interacting theory we deform the time integration so it has some evolution in euclidean time. We explicitly give the results for the 3- and 4-point functions,

$$I_3 = \frac{8}{9} - \frac{\sum_{i<j} 2k_i k_j}{k_t^2} - \frac{1}{3}(\gamma + N_{k_t}) \frac{\sum_i 2k_i^3}{k_t^3} \quad (25)$$

$$I_4 = \frac{8}{9} - \frac{\sum_{i<j} 2k_i k_j}{k_t^2} + 2 \frac{\prod_i k_i}{k_t^4} - \frac{1}{3}(\gamma + N_{k_t}) \frac{\sum_i 2k_i^3}{k_t^3}$$

where $\gamma = 0.577216$ is the Euler's constant and $N_{k_t} = \ln(|k_t \eta_{reh}|)$ is the number of e-foldings from the time k_t crossed the horizon ($k_t \eta = -1$) to the time of reheating.

The value of I_N is dominated by the term proportional to N_{k_t} because the modes that we observe left the horizon roughly 60 e-foldings before the end of inflation. This has a very simple interpretation. All terms in equation (25) are of order one except for that proportional from N_{k_t} . They represent the effect of the self-coupling on the modes as they are being generated, at horizon crossing during inflation. The terms proportional to N_{k_t} however originates from the classical evolution of the field outside the horizon. To see this in a concrete example lets consider the corrections induced by classical outside the horizon evolution of a field with a small third and fourth order coupling. We will write $\delta\phi(\mathbf{x}) = \delta\phi_{(0)}(\mathbf{x}) + \delta\phi_{(1)}(\mathbf{x}) + \dots$ where $\delta\phi_{(0)}(\mathbf{x})$ denotes the Gaussian fluctuations that are produced in the absence of these couplings, $\delta\phi_{(1)}(\mathbf{x})$ the first order corrections, etc. We can neglect spatial derivatives and assume the field is slowly rolling so that,

$$3H\dot{\delta\phi}_{(1)} = -\frac{V^{(3)}}{2!}\delta\phi_{(0)}^2 - \frac{V^{(4)}}{3!}\delta\phi_{(0)}^3. \quad (26)$$

Thus in de-Sitter space (H constant)

$$\delta\phi_{(1)} = -\frac{N}{3H^2} \left[\frac{V^{(3)}}{2!} \delta\phi_{(0)}^2 + \frac{V^{(4)}}{3!} \delta\phi_{(0)}^3 \right]. \quad (27)$$

where we have introduced the number of e-foldings $N = H\Delta t$. The three and four point functions implied by these expressions are exactly the same as those corresponding to the terms proportional to N_{k_t} in equation (25). A discussion of the non-Gaussianities generated by

outside the horizon classical evolution of a scalar field, in the context of a multicomponent inflationary model can be found in [8].

The physics is very simple, the self-couplings of the field creates higher order correlations in two different ways. It modifies the the statistics of the fluctuations themselves but it also changes the Gaussian part of the fluctuations as the field evolves outside the horizon. Because we are considering the evolution outside the horizon it is local in real space, meaning that it leads to non-Gaussianities of the form,

$$\delta\phi = \delta\phi_{(0)} + a_2\delta\phi_{(0)}^2 + a_3\delta\phi_{(0)}^3 + \dots \quad (28)$$

There are deviations from this “local” approximation coming from the fact that N_{k_t} varies across the scales we observed, it changes by roughly 10 % between the CMB scales and smaller scales that one could access by studying large scale structure. There are also corrections of order $1/N_{k_t}$ due to the non-Gaussianities produced at the time the fluctuations crossed the horizon during inflation. Those have different configurational dependance.

We should also point out that the non-linearities keep acting all the way until reheating, even after the universe stopped inflating. During the period of matter domination, what determines the growth is,

$$\int \frac{dt}{H} \approx \frac{3}{2H_{reh}^2} = \frac{3}{2\Gamma^2}, \quad (29)$$

where we have just taken $H \sim 2/3t$ during the period between the end of inflation and reheating and used $H_{reh} = \Gamma$. Thus we should replace the number of e-foldings in equation (27) by an effective number $\tilde{N}_{k_t} = N_{k_t} + 3/2(H/\Gamma)^2$ with H the Hubble constant during inflation.

We will concentrate on the three point function because unless ϕ is fluctuating very close to the origin, so that $\delta\phi/\bar{\phi} \sim 1$ the four point function will be smaller. In fact one naturally expects $\langle \mathcal{R}^4 \rangle / \langle \mathcal{R}^3 \rangle \langle \mathcal{R}^2 \rangle^{1/2} \sim \delta\phi/\bar{\phi}$. For our simple one field example the contribution to $f_{NL}^{\mathcal{R}}$ due to non-linearities in the potential is,

$$f_{NL}^{\mathcal{R}} = -\frac{\bar{\Gamma}}{\Gamma_1\alpha} \frac{V^{(3)}\bar{\phi}}{3H^2} \tilde{N}_{k_t} \quad (30)$$

To make an estimate of the size of these non-Gaussian contribution we will relate $V^{(3)}$ to $V^{(2)} = m^2$ and rewrite,

$$f_{NL}^{\mathcal{R}} = -\frac{\bar{\Gamma}}{\Gamma_1\alpha} \left(\frac{V^{(3)}\bar{\phi}}{m^2} \right) \left(\frac{2m^2}{3H^2} \right) \frac{\tilde{N}_{k_t}}{2}. \quad (31)$$

We now notice the in the presence of a mass term the evolution of the modes outside the horizon ($3H\dot{\phi}_{(1)} = -m^2\delta\phi_{(0)}^2$) creates a scale dependance of the power spectrum because larger wavelengths that came out the horizon earlier had a longer time to evolve and thus have a smaller amplitude at reheating. This is exactly the same

as what happens in the curvaton scenario [12]. The power spectrum gets a blue tilt from this effect,

$$(n-1)^{\text{mass}} = \frac{2}{3} \frac{m^2}{H^2} \quad (32)$$

so that,

$$f_{NL}^{\mathcal{R}} = -\frac{\bar{\Gamma}}{\Gamma_1\alpha} \left(\frac{V^{(3)}\bar{\phi}}{m^2} \right) (n-1)^{\text{mass}} \frac{\tilde{N}_{k_t}}{2}. \quad (33)$$

Departures from scale invariance are observed to be small, that is $n-1$ should be smaller than $\text{few} \times 10^{-2}$ while $\tilde{N}_{k_t}$ is of order 60-100. If the factor $m^2/3H^2 \times \tilde{N}_{k_t} \sim 1$ and $V^{(3)}\bar{\phi}/m^2 \sim 1$ then the non-Gaussianities produced by the self couplings are of the same order than those produced by the non-linear relation between the fluctuating field and the decay rate. To put it another way, even though $V(\phi)$ does not have to satisfy slow-roll conditions, if the spectrum of perturbations is nearly scale invariant then the non-Gaussianities are not expected to be larger than current observational constraints.

We can consider a simple example $V(\phi) = \lambda\phi^4/4!$ and assume that inflation has lasted long enough before the scale of our present horizon crossed the horizon during inflation, that the field ϕ has rolled to the point in the potential where the change during one e-folding in the classical trajectory equals the quantum fluctuations $H/2\pi$. This point corresponds to $\bar{\phi} \sim \lambda^{-1/3}H$. In that case $(n-1)^{\text{mass}} \sim \lambda^{1/3}$. Thus constraints on the spectral index already put $\lambda < 10^{-6}$. Moreover $\delta\phi/\bar{\phi} \sim \lambda^{1/3}/2\pi$ so to match the observed $\mathcal{R} \sim 4 \times 10^{-5}$ we need $\Gamma_1\alpha/\bar{\Gamma} \sim 10^{-4}/\lambda^{1/3}$. The non-Gaussianity parameter is then,

$$f_{NL}^{\mathcal{R}} \sim -3 \cdot 10^3 \lambda^{2/3} \tilde{N}_{k_t}. \quad (34)$$

So for example if $\lambda^{1/3} \sim 10^{-2}$ and $\tilde{N}_{k_t} \sim 100$ we get $f_{NL}^{\mathcal{R}} \sim -30$ very close to the limit set by WMAP.

IV. SUMMARY

We have discussed the different sources of non-Gaussianities in the scenario introduced in [16]. In this section we summarize the results and make contact with observations. In most of the observational studies so far, in particular in the latest constraints from WMAP [22] the analysis was done in terms of the non-Gaussianities in the gravitational potential during the matter dominated era, $\Phi = -3/5\mathcal{R}$. Constraints were set on f_{NL}^{Φ} defined by,

$$\Phi = \Phi_g + f_{NL}^{\Phi}(\Phi_g^2 - \langle \Phi_g^2 \rangle) + \dots \quad (35)$$

Thus $f_{NL}^{\Phi} = -5/3 f_{NL}^{\mathcal{R}}$. WMAP constrained $-58 < f_{NL}^{\Phi} < 134$ at 95 % confidence [22].

Non-Gaussianities in this scenario can have several sources. There are contributions that are proportional to $\bar{\Gamma}/\Gamma_1\alpha$. These come from corrections that are directly proportional to $\delta\phi/\bar{\phi}$, either from non-linearities in the relation between $\delta\Gamma/\bar{\Gamma}$ and $\delta\phi/\bar{\phi}$ or intrinsic non-Gaussianities due to a cubic self interaction of the field. In the simple examples we have presented, the first contribution is $f_{NL}^\Phi = 5/12 (\bar{\Gamma}/\Gamma_1\alpha)$. The WMAP constraints already imply that $\Gamma_1/\bar{\Gamma} > 0.1$. The contribution from the self couplings, equation (30), combined with the WMAP constraints imply that $\tilde{N}_{kt} V^{(3)}/H < 0.1$.

There are non-Gaussianities coming from the non-linear relation between $\mathcal{R}$ and $\delta\Gamma/\bar{\Gamma}$. These grow as the generation of density perturbations becomes more inefficient, that is as $\bar{\Gamma}/H$ grows but they are not proportional to $\bar{\Gamma}/\Gamma_1$. In the limit $\bar{\Gamma} \ll H$ this contribution is $f_{NL}^\Phi = -5$ and is larger if $\alpha < 1/6$.

Finally, all these contributions should be interpreted as additions to the $f_{NL}^\Phi \sim 1$ coming from second order GR effects which we have not considered here. For effects produced when modes are crossing the horizon (either on the way out or in) spatial gradients will not be negligible so the configuration dependence of the three point function will be different than in the simple f_{NL} model. These corrections are independent of the efficiency of our mechanism to translate $\delta\phi/\bar{\phi}$ into $\mathcal{R}$ and thus are expected to be the smallest.

A few general conclusions of our study are worth emphasizing. First as noted above, inefficiencies in the translation between field fluctuations and curvature perturbations increase the expected non-Gaussianities. Second, the non-Gaussianities in our model are mainly generated when the modes of interest are outside the horizon. As a result it is natural to look for departures from Gaussianity that are “local” in real space, meaning of the form $\mathcal{R} = \mathcal{R}_g + f_{NL}^\mathcal{R}(\mathcal{R}_g^2 - \langle \mathcal{R}_g^2 \rangle) + \dots$. If the decay rate is determined by more than one fluctuating field there could be additional corrections at the second order in $\mathcal{R}$, but these are irrelevant if one is interested only in N-point functions to leading order in f_{NL} (the actual expansion parameter is $f_{NL}^\mathcal{R}\mathcal{R}$ so higher order terms are very small). The “local” approximation should be excellent in these models. Third because our mechanism is in some sense somewhat inefficient ($\alpha < 1/6$, $\Gamma_1/\bar{\Gamma} < 1$), $f_{NL} \sim \text{few}$ is guaranteed in our scenario even if the fluctuations in the fields are intrinsically Gaussian. This last point is of particular interest because $f_{NL} \sim \text{few}$ corresponds to the expected sensitivity of future CMB experiments [19] and the standard inflationary scenario predicts corrections much smaller than these [6]. If the efficiency of the mechanism is decreased or if self interactions are important, the level of non-Gaussianities can be increased to saturate the current upper limits. However the fact that the spectrum of perturbations is close to scale invariant, implies that even in the presence of self-couplings the natural level of non-Gaussianities is somewhat below the current limit although not far from it.
